Explanations of Heterogeneity in Selection in Bangladeshi Migrants into Construction Labor Market in Singapore

Motivation

In the coming months, I will answer the question of what characteristics explain the heterogeneity in selection of workers from Bangladesh into the Singaporean construction market and its effects on long-run dynamics and equilibrium. There are several seemingly unique characteristics of this market, such as high worker turnover as well as high and highly varied middleman fees (see summary statistics under econometric estimation section). After identifying the causes of selection, as outlined in the econometric procedures section, I will estimate the implications on the selection process on long-run equilibrium.

The majority, close to 70 percent, of Singapore's non-resident working population, numbering around 1.6 million workers, consists of low-skilled migrant labor (National Population and Talent Division 2011). Laborers are generally recruited from their home countries to a network of agencies and then matched with an employer. These workers are almost always temporary, remit much of their income, and live within modest means in Singapore. Additionally, many migrant workers have little to no grasp of English, the official language, which may cause a great deal of asymmetric information in these markets. The same implications can also be extrapolated to many other cities with large migrant workforces; other migration contexts where the same general process may apply includes migration to the Gulf States in the Middle East.

The characteristics of the labor market could be explained by the selection process of laborers into the market. The recruitment process for these workers is very different to conventional mechanisms of search and matching generally seen in the labor market. First, an employer with a certain number of vacancies sends a demand letter to an agent in Singapore for these vacancies to be filled. Next, the agent in Singapore will contact a counterpart in the migrant-origin country, who will then contact or send an agent to recruit from a village. The migrant will pay a fee to the third agent in the chain, who will then send the migrant's information back through the chain. The migrant will be provided with a short period of training to learn basic construction skills before being matched with an employer and provided an IPA (In-principle agreement), giving him his wage and length of contract. If the migrant agrees, he is then sent to Singapore and works under what is generally a one or two-year contract. After his contract the migrant generally returns to his country of origin and may have to reenter the process if he wants to find another job in Singapore.

Approach

Initially, I will identify the causes of selection based on basic assumptions about the labor recruitment market. Bangladesh was chosen due to the availability of data, large number of migrants in many destination countries, prior institutional knowledge, and the importance of migration on both Bangladesh's and Singapore's economies. After the cause of selection is found, then a theoretical model will be developed to give the implications on productivity and wages of workers in the long-run.

Literature Review

Papers that have influenced the model formation and empirical estimation at this stage include "Equilibrium Wage and Dismissal Processes" (Flinn 1997), and "Middlemen", which gives a basic structure and role of middlemen in the exchange process (Rubinstein, Wolinsky 1987). Flinn's 1997 paper explains labor market dynamics based on productivity and information asymmetry; I intend to model the structure of my paper on his. At a more basic level, another theoretical paper used in modeling selection based on productivity and information is "Games with Incomplete Information Played by "Bayesian" Players" (Harsanyi, 1967). In addition, "Asymmetric Information and Intermediation Chains" gives a general result that could be

Asymmetric information and intermediation chains gives a general result that could be possible in this context, where there is trade under asymmetric information with long intermediation chains (Glode, Opp 2016). Although not a piece of economics literature, *Bangladeshi Migration to Singapore*, a sociological analysis, gives an immense amount of information on migration networks and institutions that inform my analysis (Mizanur Rahman 2017).

Contributions

Research in migration channels contributes to understandings of intermediation and provides either an example of efficiency loss or an approach of curtailing high search costs. If the analysis of selection does result in demonstrated deadweight-loss, this would be a demonstration of the results of “Asymmetric Information and Intermediation Chains” (Glode, Opp 2016). If we see a result that demonstrates efficient selection, then it is a demonstration of efficient outcomes under adverse-selection, which runs contrary to the standard model outcomes.

In addition to applications of theoretical models, this analysis would also add to the literature on developmental impacts of migration and migrant characteristics (See the work of Dean Yang or David McKenzie). However, there has not been as much of a focus on the middlemen intermediation networks of migration itself. Understanding these networks is crucial in understanding the developmental impacts of migration.

Econometric Procedures in Estimating Heterogeneity in Selection

Data Sources:

Currently, I have access to three sources of data: a work history survey done by a migrant advocacy non-profit, a smaller set I personally collected, and a migrant household survey done by the International Organization of Migration and UK Department for International Development. I will attempt to get access to a migrant household survey done in Bangladesh in 2013 by the International Organization of Migration (IOM) and the UK Department for International Development (DFID). The dataset I personally collected, in June and July of 2016, is small, with 142 samples, 126 of which are from Bangladesh. This was from a one-time survey, giving information on migrant age, education, wage, agency fees, years worked in Singapore, company, and remittances. The dataset collected by the NGO has 910 samples collected in November 2015 to May 2016, 407 of which are workers from Bangladesh. This survey is also cross-sectional and gives information on previous migrations and salary history of migrants. The IOM and DFID survey samples 1200 migrant households from Bangladesh, of which 527 are international migrants.

Estimation and Tests

Under the assumption of middlemen as monopolists practicing first-degree price discrimination, there are at least four possible sources in heterogeneity from agency fees. The four possible explanations I have identified are

- Productivity
- Reservation Wage
- Information
- Risk Preference

For the first possible explanation, productivity, it is assumed that productivity is observable, while for the latter three, productivity is assumed unobservable. Even if we assume productivity to be observable in the latter three instances, it does not make a significant difference on the econometric estimation. Each explanation of selection will have different implications regarding sector productivity. After the most fitting explanation for selection is identified, long-run dynamics and equilibrium will be tested. The test for each explanation and the implications is as follows:

Productivity:

If we assume that, under perfect information, productivity is the source of heterogeneity in migrants, this would have two testable implications. For one, workers who have already worked in the market would be willing to pay more, as they are assumed to be more productive. Secondly, wages and middlemen fees would be positively correlated. If this explanation is the case, then there is no productivity loss from the middlemen recruitment chain.

Tests:

1)
2)

- W: Wage
- f: Middleman Fee
- X: Years worked
- Y: year of migration

If productivity explains selection, then , and .

Reservation Wage:

It may be the case that workers with lower reservation are more likely to pay more for a job overseas. We assume that credit markets are operational (a fair assumption as almost all workers take loans for middleman fees), and workers with poorer opportunities would be willing to take pay higher fees for more lucrative opportunities overseas. For these tests, we assume productivity to be uniform, productivity to be unobservable, and wages to be a lottery. Workers are assumed to have knowledge of the wage distribution.

The test is simple, a regression of pre-migration income (Q33 on Migrant Household Survey) to agency fees. Regarding implications on returning migrants, it is reasonable to assume reservation wage would increase with future migrations, as remittance money would improve living conditions at home (an assumption that will also be tested). If reservation wage increases, then previous migrants would be less likely to re-enter the market.

Tests:

1)

- W_p : pre-migration wages (Q33 in Household Survey)

If reservation wage explains selection, then

2)

- Q: Quality of life, self-reported (Q67 in Household Survey)
- M: indicator variable (1=migrant, 0=non-migrant)
- W: wage

If , then once again test:

1)

If reservation wage explains selection, then

Information

In qualitative literature, there are descriptions of middlemen targeting more naïve potential workers to charge a maximum possible agency fee. For these tests, we assume productivity to be uniform, and wages to be a lottery. Potential workers are assumed to have different expectations of wages.

If this it is the case that heterogeneity is from imperfect information, there will be many characteristics of the selection and migration that differ from the above explanations Firstly, wages and agency fees paid will be uncorrelated; secondly, repeat migrants would be willing to pay lower fees than first-time migrants; Thirdly, we would see the share of returning migrants steadily decrease over time. Also, if information asymmetry were the explanation, workers who had prior contacts or knew someone in the foreign labor sector, other than a middleman, would be willing to pay less than those who did not have such connections.

Tests:

1)

2)

Retesting this regression, if information asymmetry explains the selection process, then , , and .

3)

- C = Connections at destination other than middleman (1=yes, 0=no)

In terms of measuring distribution to confirm or reject this hypothesis, we would measure the kurtosis of the distribution and using a quantile-quantile plot against a normal distribution to compare skewness.

Risk Preference

It is possible that workers who are more risk-loving are more willing to take the gamble of working overseas. Although there is no direct empirical measure of risk aversion, risk measure can be reasonably proxied by the number of household members and dependents. The

can be reasonably predicted by the number of household members and dependents. The assumptions uniform productivity and wage determination as a lottery still hold. Risk-loving workers would be willing to pay more to enter the lottery, with knowledge that wage is effectively random. If this is the case, we would once again see no correlation between wage and middleman fees. However, we should see agency fees decrease as the number of dependents increases. Also, controlling for dependents, the distribution of workers by experience should be a uniform distribution, if we assume risk profiles remain constant over time.

Tests:

1)

- D: Dependents
- M: Married (0 = single, 1 = married)
- A: Age
- X: years worked

If risk preference is the cause of selection, then controlling for age and years in the labor force, . Also testing the distribution of workers, using kurtosis and a Q-Q plot, should show a uniform distribution.

Theoretical Framework

Given the results of the econometric estimation, there will be a different set of models for long-run equilibrium. If productivity can be observed and explains selection heterogeneity between migrants, then the market will be modelled as the first-best production outcome under a standard principal-agent model: a complete information optimal contract. Otherwise, in any of the three explanations, it will be modelled a dynamic game with three sets of actors.

Model Primitives (Productivity)

-Actors: N Principals (aggregation of firms and middlemen), K Agents, $K \gg N$

-Payoffs:

1. Agent's Cost Function:

a. Payoff: $u(W) = u((w - q))$

2. Principal's Payoff:

a. At equilibrium,

-Timing: Static Game: $t=0$, agent (worker) discovers type; $t=1$, Principal offers contract; $t=2$, agent accepts or refuses contract; $t=3$, contract executed

Model Primitives (Reservation Wage or Information Asymmetry)

Actors: K workers, Employers (aggregated as "B"), Middlemen (aggregated, denoted "M")

- Heterogeneity: workers expected payoff of working, cumulative distribution function denoted $G(x)$

Payoffs: (See attached document)

- Attached model only factors information asymmetry, but the long-run outcomes are similar for reservation wage

Timing: Dynamic game,

- Changes between states: exogenous retention rate τ and discount factor β

Theoretical model with long-run outcomes under selection for risk is forthcoming
